

1. Linear Regression: I learnt how to implement linear regression properly for a dataset. There were some missing values in the original dataset, so I had to preprocess it by filling the missing values with the median of the entire column. Next step is to fit our linear regression model with the values of input and output to train our model. We then find out the values of our coefficients and our intercept and now we can predict the output for any input.
2. Logistic Regression: While making this model I learnt how to properly carry out logistic regression for a given dataset. We first start to preprocess our data to fill the missing values. We fill the integer and float missing values with the median and fill the string missing values with the mode of the columns. We then make our logistic regression model and fit it with different parameters and also the output(0 or 1) to train our data. We then open another dataset and preprocess it. We use the new dataset to test our model. We try to predict the outcome (0 or 1) corresponding to the input parameters in the test dataset. We then open a third dataset which contains the actual outcomes and then compare how accurate are model is. The score of 1 is considered perfect and our model has a score of 0.935
